ABSTRACT

1. INTRODUCTION

The storage of user generated content within systems has introduced vast amounts of data. To clean the dump an important task is entity resolution. Entity Resolution (ER) is the problem of resolving the records in a data set that correspond the same real world entity.

Entity resolution is a notoriously computationally difficult problem. Several efforts in different domains have made outstanding progress []. The main issues still affecting runtimes of ER systems are twofold, first, the computation of large entities and second, excessive computation spent resolving unambiguous entities. Optimization that touches these difficult points is wholly understudied. Amdahl's argument suggests that compression and approximation techniques can efficiently decrease the runtimes of traditional ER systems.

Some recently, researchers have suggest methods of compressing entities. Wick et al Heirchical ... Singh et all efficient facttoring http://people.cs.umass.edu/sameer/files/mcmcmemnlp12-ppt.pdf

4. PROBLEM STATEMENT

In this section we formally define the compression problem for entity resolution.

We have two problems. First, Given an Entity \mathcal{E} how can we create a a structure with minimal total size. Second, How can we incrementally add and remove items from the compressed structure. Third, how can we iterate over or sample from the compressed data structure to perform uncompression.

Show Distribution of Entity sizes in the data set

We can take advantage of the redundancy within large entities and compress the entities.

We look to perform add, remove and iterate operations over the compressed entity sets.

5. ALGORITHMS

In this section we will describe XXX algorithms for entity sampling. The main method we use to improve the computation speed is to reduce the number of comparisons we make for large entity clusters. We additionally discuss methods to improve the performance of algorithms over time by collecting statistics from the processes.

Random Iterator. This method shuffles the mentions in both the source and destination entity clusters when doing pairwise comparisons.

Sorted Iterator. This method sorts them mentions in both the source and destination entity clusters when performing pairwise comparisons.

SubSample Iterator. This method only samples M mentions from the source and destination entities clusters when performing pairwise comparisons.

Top-K SubSample Iterator. This method uses a priority queue to sort the mentions and only performs comparisons for the first M values.

Blocked Iterator. This method performs blocking on the mentions in the source and destination entities and takes the average gain from pairwise comparisons inside each block

Further, We examine active learning techniques to adjust threshold sizes based on statistics collected while running the algorithms.
